#### **Abstract**

The laminar combustion characteristics of  $CH<sub>4</sub>/air$  premixed flames with  $CO<sub>2</sub>$  addition are systemically studied. Experimental measurements and numerical simulations of the laminar burning velocity (LBV) are performed in  $CH_4/CO_2/A$ ir flames with various  $CO<sub>2</sub>$  doping ratio under equivalence ratios of 1.0–1.4. GRI 3.0 mech and Aramco mech are employed for predicting LBV, adiabatic flame temperature (AFT), important intermediate radicals (CH<sub>3</sub>, H, OH, O) and NO<sub>x</sub> emissions (NO, NO<sub>2</sub>, N<sub>2</sub>O), as well as the sensitivity analysis is also conducted. The detail analysis of experiment and simulation reveals that as the  $CO_2$  addition increases from 0% to 40%, the LBVs and AFTs decrease monotonously. Under the same  $CO_2$  doping ratio, the LBVs and AFTs increase frst and then decrease with the increase of equivalence ratio, and the maximum of LBV is reached at equivalence ratio of 1.05. The mole fraction tendency of important intermediates and NO<sub>x</sub> with equivalence ratio and CO<sub>2</sub> doping ratio are similar to the LBVs and AFTs. Reaction H+ O<sub>2</sub>  $\Leftrightarrow$  O+OH is found to be responsible for the promotion of the generation of important intermediates and NO<sub>x</sub> under the equivalence ratios and CO<sub>2</sub> addition through sensitivity analysis. The sensitivity coefficients of elementary reactions that the increasing of  $CO<sub>2</sub>$  doping ratio promotes or inhibits formation of intermediate radicals and NO*x* decreases.

# **1 Introduction**

Carbon dioxide  $(CO_2)$  and methane are responsible for global warming and climate change. Human beings must solve a series of problems related to global warming, and greenhouse gas emissions is the main factor leading to this problem (Wang et al. [2021;](#page-17-0) Li and Fang [2014](#page-16-0)). In order to cope with the high  $CO<sub>2</sub>$  concentration in the atmosphere, it is necessary to reduce carbon emissions through various methods.  $CO<sub>2</sub>$  capture and utilization have attracted more and more attention, such as  $CO<sub>2</sub>$  capture (Talapaneni et al. [2019](#page-17-1); Huang et al.  $2019$ ) and conversion of  $CO<sub>2</sub>$  to hydrocarbons (Ao et al. [2020;](#page-16-2) Guo et al. [2019](#page-16-3); Zhang et al. [2021](#page-17-2); Shamiri et al.  $2016$ ). Besides, exploring the effect of  $CO<sub>2</sub>$  dilution on the fuel combustion (e.g., hydrocarbons, synthesis gas, biogas, etc.) is also one of the important research felds. Exhaust gas recirculation (EGR) has been shown to be an effective method to reduce  $NO<sub>x</sub>$  emissions and improve burst resistance. EGR contains gases consisting a large amount of  $CO<sub>2</sub>$ , and EGR affects the combustion process through three pathways:  $(1)$  thermal,  $(2)$  dilution, and  $(3)$  chemical effects (Wang et al.  $2022$ ).  $CO<sub>2</sub>$  is also required as a diluent for both moderate and intense low oxygen dilution combustion and oxyfuel combustion (Liu et al. [2020](#page-16-4)). Methane, as the simplest hydrocarbon fuel, is of great theoretical and practical importance for the study of its blending and combustion with  $CO<sub>2</sub>$ . Laminar combustion is the basis of turbulent combustion and the cornerstone of further study of combustion and it can refect various combustion characteristic parameters such as laminar burning velocity, ignition energy, maximum

fame temperature, ignition delay, ignition temperature and concentration of fuel (Movileanu et al. [2011\)](#page-17-5). Laminar burning velocity (LBV) is an inherent characteristic of fuel and an important parameter for laminar fame propagation and stability. Laminar burning velocity depends on the type and composition of fuel and initial conditions such as equivalence ratio, pressure and temperature, and contains important information such as reaction, difusion, heat release, tempering, instability, etc. (Chu et al. [2020](#page-16-5); Nonaka and Pereira [2016](#page-17-6); Zhang et al. [2015](#page-17-2)). It's a very vital parameter in the design effective control of combustion systems, such as the design and manufacture of combustors and explosion suppression devices, and the optimization of internal combustion engines (Hu et al. [2009a,](#page-16-6) [b](#page-16-7); Dirrenberger et al. [2011](#page-16-8); Razus et al. [2010](#page-17-7); Ren et al. [2019a,](#page-17-8) [b;](#page-17-9) Chu et al. [2019](#page-16-9)).

Sampath et al. ([2023](#page-17-10)) investigated the effect of  $CO<sub>2</sub>$  on the laminar burning velocity of  $CH<sub>4</sub>/air$  at high temperatures by using the externally heated diverging channel (EHDC) method. It was shown that the dilution of  $CO<sub>2</sub>$  enhances the competition for H-atom consumption, and the LBV increased with the increase of the mixture and decreased with the proportion of doped  $CO<sub>2</sub>$ . Ghabi et al. [\(2023](#page-16-10)) studied the efect of microsecond pulsed plasma on non-premixed biogas. Shang et al. [\(2022\)](#page-17-11) systematically investigated the effect of  $N_2/CO_2$  on  $H_2/CH_4/air$  laminar flame velocity. Ueda et al.  $(2021)$  $(2021)$  explored the effect of  $CO<sub>2</sub>$  on the premixed combustion characteristics of methane/air using the spherical expansion method. Jithin et al. ([2020\)](#page-16-11) investigated the combined effect of  $CO<sub>2</sub>/N<sub>2</sub>$  dilution on the laminar combustion rate of methane/oxygen by heat fux method and numerical simulation. The results showed that the laminar burning velocity decreased with increasing proportion of blended  $CO<sub>2</sub>$  and it is found that the laminar burning velocity decreased more in the fuel-rich combustion case than in the fuel-lean combustion and stoichiometric ratio. Anggono et al. (2020) investigated the effect of  $CO<sub>2</sub>$  concentration on the laminar burning velocity and Markstein length of  $CH<sub>4</sub>/$ air premixed fames at high pressure constant volume combustion. It was shown that there is a monotonic relationship between the Markstein length and the  $CO<sub>2</sub>$  dilution ratio and that the unstretched laminar burning velocity of the mixture decreased with increasing  $CO<sub>2</sub>$  concentration. Azatyan et al.  $(2010)$  $(2010)$  reported the effect of CH<sub>4</sub>, N<sub>2</sub>, CO<sub>2</sub> and steam addition on the LBVs of  $H_2$ . The predictions showed that with the increase of  $H_2$  doping ratio, the LBVs of  $H_2/A$ ir monotonically decreased, but did not exceed 1.5 times, and the AFTs changed slowly. The effect of  $CO_2$  and  $N_2$  on the fame stability and LBVs of syngas/air was successfully performed by Burbano et al. [\(2011](#page-16-13)). Through experimental and numerical simulations, Burbano et al. ([2011\)](#page-16-13) showed that with the increase of  $CO<sub>2</sub>$  dilution doping ratio, the LBVs decreased obviously due to the decrease of heat release and the increase of heat capacity. This conclusion was consistent with the conclusion of Ref. Wang et al. ([2012](#page-17-12)) measured the LBVs of  $CO/H<sub>2</sub>/CO<sub>2</sub>/O<sub>2</sub>$  by using spherical flame. The experimental results proved that  $H_2$  and  $CO_2$  have opposite effects on the LBV of syngas. Sun and Xu  $(2020)$  $(2020)$  conducted the relationship between turbulent burning velocity and  $H_2$ content in synthesis gas and revealed that turbulent burning velocity was a second-order polynomial of hydrogen volume fraction. Based on heat fux method and Bunsen burner, Wang et al. [\(2015\)](#page-17-13) measured the LBVs of  $CO/H_2/N_2/CO_2$ and numerically analyzed the efect of H and OH radicals on the LBV of syngas. The results showed that H had a linear relationship with LBVs. Nonaka and Pereira [\(2016\)](#page-17-6) studied the effect of  $CO<sub>2</sub>$  addition in biogas on LBVs. The LBVs and other combustion characteristics of the natural gas blended with  $N_2$ , CO<sub>2</sub> and H<sub>2</sub>O were carried out by Ren et al. ([2019a,](#page-17-8) [b](#page-17-9), [2020\)](#page-17-14). In addition, the effects of  $CO_2$  on  $NO_x$  formation of methane combustion products were also conducted. Xiang et al. [\(2019](#page-17-15), [2020](#page-17-16)) numerically investigated the chemical and physical effects of  $CO<sub>2</sub>$  and  $H<sub>2</sub>$  on LBVs and other laminar combustion characteristics of  $CH<sub>4</sub>$ .

In view of the above considerations, the frst objective is to investigate the effect of blending a wide range of  $CO<sub>2</sub>$  concentrations on methane combustion characteristics through a combination of experimental and numerical simulations. The second objective is to analyze the effect of  $CO_2$  on  $NO_x$ generation during methane combustion, from the molar amount of  $NO<sub>x</sub>$  to the temperature sensitivity of  $NO<sub>x</sub>$ . There have been many studies on the effect of  $CO<sub>2</sub>$  on methane combustion characteristics, but few have addressed the efect of  $CO<sub>2</sub>$  blending into methane in terms of temperature sensitivity and  $NO<sub>x</sub>$  generation. Therefore, this work conducts a study on the laminar combustion characteristics and NO*<sup>x</sup>* emission of methane blended with  $CO<sub>2</sub>$ .

#### **2 Experiment setup**

The laminar premixed fame experimental system is shown in Fig. [1.](#page-3-0) The experimental systems were mainly divided into: Bunsen burner, gas delivery system, gas supply system and safety system. The Bunsen burner mainly consists of a lamp body section and a lamp nozzle connected. The inner cavity of the lamp body section is equipped with a packing layer, a flow equalizing plate and a sintered net from bottom to top. The device plays a role in stabilizing the fow of the gas mixture fowing through it, and the fame ignited from the lamp nozzle is close to being conical, so that the detection accuracy of the fame propagation speed can be improved. The gas delivery system is completed by mass fow controller (MFC) and mixing tank. The brand of MFC is Sevenstar Huachuang CS200 series with an accuracy of 0.35% of full scale. The gas supply system contains  $N_2$ ,  $CO_2$ ,  $O_2$  and CH<sub>4</sub> and the purity of

<span id="page-3-0"></span>

 $CH_4$ ,  $N_2$ ,  $CO_2$  and  $O_2$  are 99.99%. The safety system is tempering valve, which is to prevent the fame from fowing back to the mixing tank to explode. After the gas through the fowmeter and mixing tank, it passes the channel at the bottom of the burner, glass beads, flow equalization plates and multi-layer metal sintering net to form a stable conical fame at the nozzle. Besides, an industrial camera is used to photograph the fame image. The fame images are obtained by a CCD camera, model MANTA G-504C manufactured in Germany. The CCD camera chip is the Sony ICX655, the response frequency range is visible light. The image acquisition is realized by connecting the CCD camera port with the computer port through a Gigabit Ethernet cable. This model of CCD camera can be very good completion of the experimental process in the acquisition of fame images.

## **2.1 CO<sub>2</sub> doping ratio**

 $CH<sub>4</sub>/CO<sub>2</sub>/N<sub>2</sub>/O<sub>2</sub>$  is studied under premixed combustion at 298 K and 1 atm. The sum of  $CH<sub>4</sub>$  and dilution is 1, that is, the content of methane in mixtures decreases with increasing dilution gas content. Therefore, the general formula for calculating the doping ratio is:

$$
\alpha = \frac{V_{\text{diluent}}}{V_{\text{diluent}} + V_{\text{fuels}}}
$$
\n(1)

where  $V_{\text{diluent}}$  and  $V_{\text{fuels}}$  are volume fractions of dilution gas and fuel, respectively.  $\alpha$  represents the proportion of dilution gas in the mixture.

Therefore, in the mixture,  $\alpha$  is defined as the CO<sub>2</sub> doping ratio, and the formula is as follow:

$$
\alpha = \frac{V_{\text{CO}_2}}{V_{\text{CO}_2} + V_{\text{CH}_4}}
$$
(2)

where  $V_{\text{CO}_2}$  is the volume fraction of CO<sub>2</sub>.  $V_{\text{CH}_4}$  denotes the volume fraction of methane in the mixture. In this paper,  $CH_4/O_2/N_2$  mixed with CO<sub>2</sub> content of 0%–40% ( $\alpha$  = 0, 5%, 10%, 15%, 20%, 25%, 30%, 35%, 40%) is systematically analyzed.

The effect of  $CO<sub>2</sub>$  on the laminar combustion of methane is different, because of the different properties of  $CO<sub>2</sub>$ and  $N<sub>2</sub>$ . During the experiment of mixing carbon dioxide with methane, we found that when the fow rates of methane were set at 280 mL/min and 260 mL/min, more experiments could be carried out. Therefore, in the experiments of mixing methane with carbon dioxide, the flow rates of methane are 280 mL/min and 260 mL/min. Table S1 in Supplementary information presents the experimental operation of  $CH<sub>4</sub>/$ Air/ $CO<sub>2</sub>$  flame.

#### **2.2 Laminar burning velocity calculation**

Figure [2](#page-4-0) shows the images obtained by CCD camera. The work conditions of  $\Phi$  = 1.2 are selected to show the images of methane mixed with carbon dioxide with doping ratios.

After capturing the images of premixed fame, the MAT-LAB code is used to calculate the LBVs of mixtures. The main steps to obtain the LBVs of  $CH<sub>4</sub>$  can be found in Ref

<span id="page-4-0"></span>**Fig.** 2 Images obtained from CCD camera under methane/air with different CO<sub>2</sub> doping ratios. **a**  $\alpha = 5\%$ . **b**  $\alpha = 10\%$ . **c**  $\alpha = 15\%$ . **d**  $\alpha = 20\%$ . **e** *α*=25%. **f** *α*=30%. **g** *α*=35%. **h** *α*=40%

(Chu et al. [2021](#page-16-14)). Figure [3](#page-4-1) gives the main steps to obtain the LBVs of  $CH<sub>4</sub>$  through the MATLAB code.

## **2.3 Error analysis**

In the process of measuring the LBVs with the Bunsen burner, the measurement error is mainly caused by the error of the total gas flow rate  $(\delta_{\Omega})$  and the error generated when calculating the flame area  $(\delta_A)$ . The error of the total flow of the premixed gas is determined by the error of methane flow rate  $(\delta_{CH_4})$ , and the accuracy of the methane flowmeter is  $\pm 2\%$  of the upset point, the error of the air flowmeter  $(\delta_{\text{air}})$ , and the error of CO<sub>2</sub> flowmeter ( $\delta_{\text{CO}_2}$ ). The accuracy is  $\pm 1\%$  of the set point. According to the error transfer principle, the error calculation method in Refs (Chu et al. [2021](#page-16-14); Moffat [1988](#page-17-17)) can be used to calculate the total gas flow error:

$$
\delta_{\mathbf{Q}} = \sqrt{\delta_{\mathrm{CH}_{4}}^{2} + \delta_{\mathrm{air}}^{2} + \delta_{\mathrm{CO}_{2}}^{2}} = \sqrt{2^{2} + 1^{2} + 1^{2}} = \sqrt{6}
$$
(3)

The error of flame area is mainly determined by the resolution of the camera and the method of experimental photo processing. By calculating the adjacent points of the

Image input Rgb<sub>2</sub>gray Grayscale conversion  $maxvalue = double(max(max(a)))$ maxvalue-x\*maxvalue Flame edge extraction  $plot(x, y, '.)$ Edge dot plot drawing  $polyfit(x,y,n)$ Curve fitting and flame area A calculation  $S_{\rm u} = Q/A$ LBVs calculation

<span id="page-4-1"></span>**Fig. 3** The major steps of calculating laminar burning velocity by MATLAB code

maximum gradient point in the inner boundary of the fame, the error is 4.5% approximately.

The total calculation error of LBV is:

$$
\delta_{\rm L} = \sqrt{\delta_{\rm Q}^2 + \delta_{\rm A}^2} = \sqrt{(\sqrt{6})^2 + (4.5)^2} \approx 5.1\% \tag{4}
$$

The calculation error of laminar burning velocity is approximately 5.1% by calculating.

## **2.4 Modeling details**

In the simulation, we choose the CHEMKIN-Pro/PRE-MIXED code to simulate the effect of  $CO<sub>2</sub>$  on methane laminar combustion. Two diferent reaction mechanisms are used for the calculations, the Aramco mech (Metcalfe et al. [2013\)](#page-17-18) and the GRI 3.0 mech (Simith et al. [2000](#page-17-19)) and these mechanisms are widely used for the calculations of small molecule hydrocarbon fuels. The Armaco mech contains 493 species and 2716 reactions and the GRI 3.0 mech contains 53 species and 325 reactions. Since the Aramco model does not include the NO*x* component, the GRI 3.0 model is used to analyze the effect of  $CO<sub>2</sub>$  dilution on  $NO<sub>x</sub>$ formation. The chemical reactions, thermal properties and transport properties database are imported using CHEMKIN format. The maximum grid number is set to 500, and the parameters chosen for this study ensured grid independence. GRAD and CURV are set to 0.04, and the iteration interval are −0.002 to 0.06 m. In addition, the Soret efect is added to the simulation. Multicomponent transport is incorporated into the reactor. Since the Aramco model does not include the NO*x* component, the GRI 3.0 mech is used to analyze the effect of  $CO<sub>2</sub>$  dilution on  $NO<sub>x</sub>$  formation.

## **3 Results and discussion**

## **3.1 Experiment and mechanism verifcation**

Figure [4](#page-5-0) shows the LBVs comparison between GRI 3.0, Aramco and San Diego mech (Prince et al. [2017](#page-17-20)) under diferent equivalence ratios. GRI 3.0 mech and Aramco mech are in good agreement with the measured LBVs of this paper and Refs. (Gu et al. [2000](#page-16-15); Bosschaart and Goey, [2004;](#page-16-16) Halter et al. [2005;](#page-16-17) Hu et al. [2009a](#page-16-6), [b;](#page-16-7) Hermanns et al. [2010;](#page-16-18) Dirrenberger et al. [2011](#page-16-8); Mazas et al. [2011;](#page-16-19) Goswami et al. [2013](#page-16-20); Akram et al. [2013;](#page-16-21) Li et al. [2015;](#page-16-22) Nonaka and Pereira [2016](#page-17-6); Mitu et al. [2017](#page-17-21); Okafor et al. [2018;](#page-17-22) Han et al. [2019](#page-16-23); Wang et al. [2020\)](#page-17-23). The yellow–brown represents lean mixture and light-cyan represents rich mixture. The predictions of San Diego mechanism (Prince et al. [2017](#page-17-20)) are in good agreement with the experimental results in fuel-lean combustion. However, when equivalence ratio  $\Phi \geq 1$ , the predictions of LBVs

<span id="page-5-0"></span>**Fig. 4** Laminar burning velocities profile for  $CH<sub>4</sub>/air$  mixture at 1 atm and 298 K for about 20 years

are lower than the experimental results. Therefore, the San Diego mechanism is not selected for prediction the combustion characteristics of methane in present work.

## **3.2 Effect of CO<sub>2</sub> addition on laminar burning velocity**

In Fig. [5,](#page-6-0) the solid red line and blue line represent the simulated results of GRI 3.0 and Aramco mech individually. Black dots indicate the LBVs of  $CH<sub>4</sub>$  measured experimentally, and gray areas represent the prediction diference between the two mechanisms. From the results of experiments and mechanism predictions, it can be seen that the predicted LBVs of the two mechanisms are not much different when  $\Phi \le 1.15$ , and the simulated values of GRI 3.0 mech are slightly larger than that of Aramco mech. However, when the  $\Phi \ge 1.15$ , the predictions of Aramco mech are higher than that of GRI 3.0 mech. Compared the predicted results of GRI 3.0 and Aramco mech with the experimental measured LBVs, it is found that the gap between experimental results and Aramco mechanism prediction results, and the errors between experiment and simulation are within 5% at same initial condition. This reveals that the process of measuring and calculating LBVs of  $CH<sub>4</sub>$ is accurate. As can be seen from Fig. [5,](#page-6-0) under the same  $CO<sub>2</sub>$  doping ratio, the LBVs ascend first and then descend with the increase of equivalence ratio, and when  $\Phi$  = 1.05, the LBVs reach the maximum. The LBVs became lower linearly as the  $CO<sub>2</sub>$  doping ratio increases. This is because the doping ratio of  $CO<sub>2</sub>$  increased, reducing the relative percentage of  $CH_4$  in the  $CH_4 + CO_2$  mixture. Another reason is that the specific heat capacity of  $CO<sub>2</sub>$  is relatively large, which will absorb part of the reaction heat (Burbano <span id="page-6-0"></span>**Fig. 5** Comparison of the measured laminar burning velocity with the simulated values

et al. [2011](#page-16-13)), resulting in the reaction rate and temperature decreased. With the increase of  $CO<sub>2</sub>$  doping ratio, the percentage of activated molecules  $(CH_4 + O_2)$  in reactant decreases, which causes the efective collision times per unit time decrease. Besides, the movement of molecules is decelerated, the number of collisions between reactant molecules per unit time presents a downward trend, and the reaction rate is decelerated. Thus, temperature and LBVs of  $CH<sub>4</sub>$  decrease. In addition, the Aramco mechanism simulation results are in good agreement with the other experiments (Nonaka and Pereira [2016](#page-17-6); Zahedi and Yousefi [2014](#page-17-16)).

<span id="page-7-0"></span>**Fig. 6** Peak values of adiabatic fame temperatures change with different  $CO<sub>2</sub>$  doping ratios

## **3.3 Adiabatic fame temperature**

Figure [6](#page-7-0) shows the effect of  $CO<sub>2</sub>$  addition on peak values of AFTs under various equivalence ratios. It can be seen that at the same  $CO<sub>2</sub>$  doping ratio, the change trend of AFTs with equivalence ratio is similar to that of LBVs. For example, when  $CO<sub>2</sub>$  doping ratio is 0.1, the AFTs are 1981.30 K, 2207.15 K and 2107.74 K at equivalence ratios of 0.8, 1.0 and 1.2, respectively.

At the same  $CO<sub>2</sub>$  addition, the AFTs decrease with the increasing of equivalence ratio, and the change trend is the same as that of LBVs. The AFTs are descended with the increase of the  $CO<sub>2</sub>$  doping ratio because the content of methane decreases, which leads to lower combustion intensity between fuel and air.

#### **3.4 Intermediates radicals**

Combustion is a quite complex process, and a series of intermediates generated in the combustion processing of methane. Based on the above view, Aramco mech was selected for predicting the effect of  $CO<sub>2</sub>$  addition on intermediate radicals under diferent conditions. In order to study the changes of the intermediate radicals with diferent working conditions, the equivalence ratios of 0.8 (fuel-lean combustion), 1.0 (stoichiometric ratio) and 1.2 (fuel-rich combustion) are chosen for simulation, respectively.

#### **3.4.1 Effect of CO<sub>2</sub> addition on CH<sub>3</sub>**

Figure [7](#page-7-1) shows the change trend of mole fraction of intermediate radical CH<sub>3</sub> with various  $CO<sub>2</sub>$  contents under different equivalence ratios.  $CH<sub>3</sub>$ , as an important intermediate, the

<span id="page-7-1"></span>Fig. 7 Intermediate radical  $CH_3$  changes with different  $CO_2$  doping ratios

maximum mole concentration is reached in the beginning of the reaction, and completely reacts in a relatively short period of time and is no longer generated.

As shown in Fig. [7](#page-7-1), firstly, keeping  $CO<sub>2</sub>$  doping ratio unchanged, the mole fraction of  $CH<sub>3</sub>$  showed a same trend with of the change of equivalence ratio. This is because the proportion of methane gradually increases with the increasing of equivalence ratio. Therefore,  $CH<sub>3</sub>$  generated in the oxidation process is gradually increasing. Because the oxidation reaction is the most intense in the slightly fuel-rich combustion ( $\Phi$ =1.05), and the AFT is the highest and the LBV is the fastest, the time of  $CH<sub>3</sub>$  mole fraction reaching maximum is frst advanced and gradually delayed with the increase of the equivalence ratio.

#### **3.4.2 Effect of CO<sub>2</sub> addition on H**

Figure [8](#page-8-0) shows the effect of  $CO<sub>2</sub>$  addition on the H under different equivalence ratios. As the basic intermediate radical, H has an indispensable relationship with LBV and AFT. It reached the maximum mole concentration at beginning of the reaction and existed in the subsequent reaction process.

Compared with  $CH<sub>3</sub>$ , under the same equivalence ratio and  $CO<sub>2</sub>$  doping ratio, the maximum mole fraction of H appeared later than  $CH<sub>3</sub>$ . This illustrates that the reaction for H formation is later than  $CH<sub>3</sub>$ . Moreover, the mole fraction of H is much larger than that of  $CH<sub>3</sub>$ .

As can be seen from Fig. [8,](#page-8-0) mole fraction of H gradually increases with equivalence ratio becomes larger under the same  $CO<sub>2</sub>$  content. The maximum mole fraction shows a trend of advancing frst and then postponing from fuelrich to fuel-lean combustion, which is consistent with that of CH<sub>3</sub>. The existence of free radical H lasts longer than  $CH<sub>3</sub>$ . There maybe two reasons accounting for this. One is that H is decomposed by  $CH_4$  continuously in the oxidation

<span id="page-8-0"></span>Fig. 8 Intermediate radical H changes with different CO<sub>2</sub> doping ratios

process. The other is that  $CH<sub>3</sub>$  also decomposes free radical H in the oxidation process, which makes radical H existed all the time in the whole oxidation process of  $CH<sub>4</sub>$ .

#### **3.4.3 Effect of CO<sub>2</sub> addition on OH**

Figure [9](#page-8-1) depicts the intermediate radical OH changes with different  $CO<sub>2</sub>$  doping ratios. OH exists all the time in the whole combustion process and gradually decreases, with a smaller decrease than that of H. It is speculated that  $O_2$ continuously participate in the reaction with  $CH<sub>4</sub>$  during the combustion process, and oxidative decomposition to generate OH. Under the same  $CO<sub>2</sub>$  doping ratio, OH generation time is advanced and then delayed as the equivalence ratio increasing.

<span id="page-8-1"></span>Fig. 9 Intermediate radical OH changes with different  $CO<sub>2</sub>$  doping ratios

<span id="page-8-2"></span>Fig. 10 Intermediate radical O changes with different  $CO<sub>2</sub>$  doping ratios

#### **3.4.4 Effect of CO<sub>2</sub> addition on O**

Figure [10](#page-8-2) shows the changes of O at different  $CO_2$  doping ratios and equivalence ratios. O as one of important intermediates, the time from the generation to the maximum mole fraction is very short, which is existed in the whole combustion process. From Fig. [10,](#page-8-2) it can also be found that at the same  $CO<sub>2</sub>$  blending ratio, the maximum mole fraction of O drops down slightly with the increasing of equivalence ratio. This is because as the equivalence ratio changes from 0.8 to 1.2, the methane keeps unchanged and the  $O_2$  decreases gradually. Thus, the proportion of O in the combustion process decreases.

## **3.5 Effect of CO<sub>2</sub> addition on generation of NO<sub>***x***</sub>**

NO*x* is main pollutant in the process of fuel combustion in internal combustion engine. The majority of nitrogen oxides emitted in combustion are NO, followed by  $NO<sub>2</sub>$  and  $N<sub>2</sub>O$ .  $NO$  and  $NO<sub>2</sub>$  can be involved in the formation of acid rain and photochemical smog in the atmosphere.  $N_2O$  is also a pollutant of interest in recent years, as it is considered a typical greenhouse gas. Therefore, it is great signifcance to investigate the effect of  $CO<sub>2</sub>$  on  $NO<sub>x</sub>$  formation during methane combustion for high efficiency and low pollution combustion. Because Aramco mech does not contain NO*x*, the influence of  $CO_2$  on methane  $NO_x$  formation is still predicted by GRI 3.0 mech. Fig. S1 in Supplementary information depicts the NO generation and AFTs of the article by using GRI 3.0 mech compared with the results of other simulation mechanisms. Fig. S2 in Supplementary information shows the NO<sub>x</sub> generation of methane mixed with different  $CO<sub>2</sub>$ doping ratio when  $\Phi$  = 0.8, 1.0 and 1.2.

<span id="page-9-0"></span>**Fig. 11** NO emissions changes with different  $CO<sub>2</sub>$  doping ratios

<span id="page-9-1"></span>**Fig. 12** NO<sub>2</sub> emissions changes with different  $CO<sub>2</sub>$  doping ratios

#### **3.5.1 Effect of CO<sub>2</sub> addition on generation of NO**

Figure [11](#page-9-0) depicts the NO generation under equivalence ratios of  $0.8$ , 1.0 and 1.2 with various  $CO<sub>2</sub>$  addition. According to Fig. [11](#page-9-0), it can be analyzed that the total NO generation decreases with the increase of  $CO<sub>2</sub>$  addition. It is presumed that the generated  $NO<sub>r</sub>$  is thermal  $NO<sub>r</sub>$ .

As can be seen from Fig.  $11$ , the equivalence ratio increases from 0.8 to 1.0, and the NO generation amount increases by 5 times. It is speculated that the equivalence ratio increases from 0.8 to 1.0, and the adiabatic fame temperature gradually increases, which results in an increase in thermal  $NO<sub>x</sub>$ .

#### **3.5.2 Effect of CO<sub>2</sub> addition on generation of NO<sub>2</sub>**

Figure [12](#page-9-1) shows the effect of various  $CO<sub>2</sub>$  doping ratio on  $NO<sub>2</sub>$  emissions at different equivalence ratios.  $NO<sub>2</sub>$ , as an intermediate, its variation trend is similar to  $CH<sub>3</sub>$ , but the difference is that the amount of  $NO<sub>2</sub>$  increases monotonously with the increase of the amount of  $CO<sub>2</sub>$ . Keeping equivalence ratio unchanged, the maximum mole fraction of  $NO<sub>2</sub>$ increases and the corresponding time of reaching maximum mole fraction later with the increase of  $CO_2$ . When  $\Phi = 0.8$ , maximum mole fraction of  $NO<sub>2</sub>$  and the time of reaching the maximum mole fraction do not change much. The highest concentration and the time of reaching highest concentration is changed obviously while  $\Phi$  = 1.2.

#### **3.5.3 Effect of CO<sub>2</sub> addition on generation of N<sub>2</sub>O**

 $N<sub>2</sub>O$  is a typical greenhouse gas, but the combustion rate can increase by the efficient use of  $N_2O$ . Figure [13](#page-10-0) depicts the changes of  $N_2O$  generation at different equivalence ratios and  $CO_2$  doping ratios. It can be seen that  $N_2O$  is an intermediate with a low mole fraction. The generation time and the time of reaching the highest mole fraction is delayed by blending  $N_2O$ , and the highest mole fraction increases.

At any equivalence ratio, the maximum  $N_2O$  mole fraction has a similar trend with the increase of  $CO<sub>2</sub>$  dilution. However, in the subsequent combustion process, the mole fraction decreases as the increasing of blending  $CO<sub>2</sub>$ .

#### **3.6 Sensitivity analysis**

In order to further reveal the impact of blending  $CO<sub>2</sub>$  on intermediate radicals and NO*x* emissions, the maximum gradient point of temperature is chosen for sensitivity analysis of the effect of  $CO_2$  addition on  $CH_4$  combustion (Dong et al. [2020](#page-16-24), [2021\)](#page-16-25). Armaco mech is used to analyze the efect of  $CO<sub>2</sub>$  addition on intermediate radicals and GRI 3.0 mech is used to analyze the effect of  $CO_2$  addition on  $NO_x$ .

#### **3.6.1 The sensitivity analysis of NO**

Figure [14](#page-11-0) describes the effect of  $CO<sub>2</sub>$  blending on NO production of methane combustion products under diferent equivalence ratios. The starting path of thermal  $NO<sub>x</sub>$  is R178  $N + NO = N<sub>2</sub> + O$  and N free radicals are quickly consumed. From the sensitivity analysis of NO*x*, it can be seen that the effect on NO production is greater than that of inhibition. R38 H + O<sub>2</sub>  $\Leftrightarrow$  O + OH and R240 CH + N<sub>2</sub>  $\Leftrightarrow$  HCN + N mainly promote the generation of NO. R35 H +  $O_2$  + H<sub>2</sub>  $\Leftrightarrow$  $HO_2 + H_2O$ , R125 CH +  $O_2 \Leftrightarrow O + HCO$  and R52 CH<sub>3</sub> + H  $(+ M) \Leftrightarrow CH_4 (+ M)$  have strong inhibitory effect on NO production at fuel-lean, stoichiometric ratio and fuel-rich combustion.

For the same elementary reaction, such as R38 H + O<sub>2</sub>  $\Leftrightarrow$  $O + OH$ , the change trend of sensitivity coefficient is consistent with the equivalence ratio. When  $\Phi = 1$ , the sensitivity coefficient of R125 CH + O<sub>2</sub>  $\Leftrightarrow$  O + HCO decreases with

<span id="page-10-0"></span>**Fig. 13**  $N_2O$  emissions changes with different  $CO_2$  doping ratios

the  $CO<sub>2</sub>$  doping ratio increases. Different from the change of intermediate radicals, for the same elementary reaction, taking R38 H + O<sub>2</sub>  $\Leftrightarrow$  O + OH as an example, the sensitivity coefficient increases continuously with the increase of equivalence ratio, rather than a trend of frst increasing and then decreasing.

#### **3.6.2 The sensitivity analysis of NO<sub>2</sub>**

As can be seen from Fig. [15](#page-12-0), diferent from the efect on NO, R38 H + O<sub>2</sub>  $\Leftrightarrow$  O + OH is to inhibit NO<sub>2</sub> generation. R52 CH<sub>3</sub> + H (+ M)  $\Leftrightarrow$  CH<sub>4</sub> (+ M) has dominant effect on promoting NO production at all equivalence ratio. In the top 10 elementary reactions, the number of elementary reactions promoting  $NO<sub>2</sub>$  generation increases first and then decreases with the increase of equivalence ratio.

At any equivalence ratio, the sensitivity coefficients of R38 H + O<sub>2</sub>  $\Leftrightarrow$  O + OH and R52 CH<sub>3</sub> + H(+ M)  $\Leftrightarrow$  CH<sub>4</sub>(+ M) increases with the increase of  $CO<sub>2</sub>$  doping ratio. And the  $CO<sub>2</sub>$  addition increases, the increase amplitude is also enhanced.

#### **3.6.3 The sensitivity analysis of N2O**

As can be seen from Fig. [16](#page-13-0), R38 H + O<sub>2</sub>  $\Leftrightarrow$  O + OH promotes  $N<sub>2</sub>O$  generation at all equivalence ratios, which is the reaction with the largest sensitivity coefficient among the top 10 elementary reactions. When the *Ф*is less than or equal to 1.0, R183 N<sub>2</sub>O + H  $\Leftrightarrow$  N<sub>2</sub> + OH mainly inhibits N<sub>2</sub>O formation, and the sensitivity coefficient does not change much with the increase of the  $CO_2$  ratio. R52 CH<sub>3</sub> + H(+M) ⇔ CH4(+M) is inhibited the generation of N2O at *Φ*=0.8,

1.0 and 1.2, and the sensitivity coefficient increases with increasing  $CO<sub>2</sub>$  addition.

#### **3.6.4 The sensitivity analysis of CH3, H, OH and O**

According to the results, when the  $CO<sub>2</sub>$  doping ratio stays unchanged, the sensitivity coefficient decreases first and then increases as the increasing of equivalence ratio. In the top 10 reactions that have a great infuence on formation of  $CH<sub>3</sub>$ , the sensitivity coefficient of reactions that promote the generation of  $CH<sub>3</sub>$  with the increase of the equivalence ratio decreases and then increases. The change trend is opposite to that of LBVs, AFTs, intermediate radicals.

At the same equivalence ratio, it can be seen in Fig. [17](#page-14-0) that the  $CH<sub>3</sub>$  sensitivity coefficient increases with the increase of the  $CO<sub>2</sub>$  addition, and the increase in sensitivity coefficient becomes larger with the increase of  $CO<sub>2</sub>$  addition. This is because with the increasing of  $CO<sub>2</sub>$  addition, the decrease in AFT gradually increasing and the sensitivity coefficient becomes larger, which means the reactions become more sensitive with temperature change. The generation of CH<sub>3</sub> is promoted by R1 H + O<sub>2</sub>  $\Leftrightarrow$  O + OH. When  $\Phi$ =0.8, R9 H + O<sub>2</sub>(+M)  $\Leftrightarrow$  HO<sub>2</sub>(+M) plays the main role of inhibition. When *Φ* is greater than or equal to 1, R127  $CH_3 + H(+M) \Leftrightarrow CH_4 + M$  has a negative effect on generation of  $CH<sub>3</sub>$ .

Figures S3–S5 in Supplementary information report the H, OH and O sensitivity coefficients with respect to the elementary reactions, respectively.

## **4 Conclusions**

In this paper,  $CO<sub>2</sub>$  is used as an additive to study its blending on the methane laminar combustion characteristics and the NO*x* emission characteristics. The study starts from studying the effect of blending a wide range of  $CO<sub>2</sub>$  concentrations on the methane combustion characteristics through a combination of experiments and numerical simulations. The second mission is to analyze the effect of  $CO_2$  on  $NO_x$  production during methane combustion from the molar amount of  $NO_x$  to the temperature sensitivity of  $NO_x$ . The reliability of the simulation results is verifed by comparing the laminar burning velocity measured by Bunsen burner with CHEMKIN simulations, with the main parameter being the laminar combustion velocity. With the increase of equivalence ratio, laminar burning velocity increases frst and then decreases. The laminar burning velocity reaches the maximum when the equivalence ratio is 1.05. GRI 3.0 mech and experimental results have good agreement in measuring the laminar burning velocity of pure  $CH<sub>4</sub>$ , but after blending  $CO<sub>2</sub>$ , the laminar burning velocity predicted by the Aramco

mechanism is highly ftted to the experimental results. The predictions of the two mechanisms are diferent. When *Φ* is less than or equal to 1.15, the prediction of GRI 3.0 mech is greater than that of Aramco mech, but when  $\Phi > 1.15$ , the predicted result by Aramco mech is greater than the simulated value of GRI 3.0 mech. At any equivalence ratio, the laminar burning velocity of  $CH<sub>4</sub>$  decreases with the increase of  $CO<sub>2</sub>$  addition. Blending carbon dioxide absorbs the heat of reaction in the combustion process, resulting in a decrease in the adiabatic fame temperature. Aramco mech is selected to analyze the effect of  $CO<sub>2</sub>$  addition to the adiabatic flame temperature, intermediate radicals, and the sensitivity analysis of the intermediate radicals, it was found that adiabatic fame temperature and the maximum mole fraction of the intermediate radicals decreases after blending  $CO<sub>2</sub>$ . Through sensitivity analysis, it is found that the elementary reaction  $H + O_2 \Leftrightarrow O + OH$  always promotes the generation of free radicals, and the sensitivity coefficient of the elementary reaction gradually decreases with the increase of  $CO<sub>2</sub>$  doping ratio. The effect of  $CO_2$  on the  $NO_x$  emissions (NO,  $NO<sub>2</sub>$  and  $N<sub>2</sub>O$ ), and sensitivity analysis of  $NO<sub>x</sub>$  formation is predicted by GRI 3.0 mech. The results of numerical simulation show that the amount of NO*x* generates or the maximum mole fraction point decreases by blending  $CO<sub>2</sub>$ . The elementary reaction  $H + O_2 \Leftrightarrow O + OH$  also always promotes  $NO<sub>r</sub>$  emission. The results of this study show the effect of  $CO<sub>2</sub>$  on methane combustion characteristics and NO<sub>x</sub> emission, which provides insight for further effective utilization of  $CO<sub>2</sub>$ . However, subsequent studies can be conducted by only verifying the effect of  $CO<sub>2</sub>$  on methane, and subsequent studies should be conducted for the blending of  $CO<sub>2</sub>$  with macromolecular hydrocarbon fuels and oxygenated fuels.
